Bounding heavy-tailed return distributions to measure model risk

João P. da Cruz · Pedro G. Lind

arXiv:1109.2803v1 [q-fin.RM] 13 Sep 2011

Received: date / Accepted: date

Abstract This article makes use of the apparent indifference that the market has been devoting to the developments made on the fundamentals of quantitative finance, to introduce novel insight for better understanding market evolution. We show how these drops and crises emerge as a natural result of local economical principles ruling trades between economical agents and present evidence that heavy-tails of the return distributions are bounded by constraints associated with the topology of agent relations. Finally, we discuss how these constraints may be helpful for properly evaluate model risk.

1 Introduction

Most of the research made on financial and economic variables has been dominated by an epistemological approach, in which the behavior of the economic system is explained by a few key characteristics of the behavior itself, like the amplitude of price fluctuations or the analytical form of the heavy-tailed return distributions (Mantegna and Stanley, 1995; Borland et al., 2005). These key characteristics motivated researchers to assume the distribution of the return of those variables as α-stable Lévy distributions or truncated α-stable Lévy distributions (Mantegna and Stanley, 1994). The logical reason for this assumption is given by the Central Limit Theorem that states that the aggregation of a growing number of random variables converges to an α-stable Lévy distribution. If these random variables have finite variances then the resulting aggregation is a 2-stable Lévy

distribution, i.e. a Gaussian distribution. If the variance of the random variables are infinite, or in the system size order, then the resulting distribution is a 2-stable Lévy distribution and the so called heavy-tailed distributions appear as a result of the aggregation. Further, from an epistemological point of view it is reasonable to assume that measurements on aggregates of human activities will result in a $\alpha-$stable Lévy distribution, since humans are too correlated with each other to show Gaussian "behavior". Henceforth, we refer to α-stable Lévy distributions with $\alpha < 2$ as Lévy distributions and with $\alpha = 2$ as Gaussian distributions.

Without leaving an epistemological approach, we could address the study of the resulting distributions by ignoring the previous arguments and construct a function that fits any set of empirical data just by building up fitting parameters until the plotted function fit the empirical data. Such approach would be the best one, if economic processes were stationary. Unfortunately they are not (Bouchaud and Potters, 2003; Sornette, 2003; da Cruz and Lind, 2010) and this means that we cannot disregard the underlying mechanisms in the analysis of empirical data. Consequently, returning to the above arguments, we are mathematically limited to α-stable Lévy distributions.

Since heavy-tails are observed in the returns of economic variables, one would expect that practitioners use Lévy distributions. Why do they use Gaussian distributions instead? There are good reasons for that. Assuming that Lévy distributions are good representations of economic variables fluctuations, a model based on it is closed when one fits the distribution to empirical data to obtain the remaining constants, to turn the mathematical model into a financial one. However, a α-stable Lévy distribution is not necessarily a good representation of future fluctuations. There is no guarantee that today's fitting will be the same as tomorrow's. Therefore, since working with a Gaussian curve is more straightforward than working with a Lévy distribution and needs less parameters for curve fitting, there is no practical gain in abandoning Gaussian distribution to model the distribution of fluctuations according to a prescribed mathematical model, even though it is not entirely correct. That is, if a Lévy distribution is fitted to empirical data of a non-stationary process one will carry basically the same model risk, as if a Gaussian distribution is used.

The differences between Gaussian and Lévy distributions as possible solutions for the distribution of financial variable values find their fundamentals in the Central Limit Theorem (CLT) (Embrechts et al., 1997; Billingsley, 1995; Mantegna and Stanley, 1995). In its classical and stronger version CLT states that a sequence of independent and identically distributed random variables with finite expected values and variance, has its sample average approaching a Gaussian distribution when the sample size is increased. Lyapunov version proves (Billingsley, 1995) that the same is valid in the case where the random variables are not identically distributed, requiring that they have moments of order greater than two and its growth rate is limited by the Lyapunov condition or Lindeberg condition (Embrechts et al., 1997; Billingsley, 1995). If the random variables are not independent, one can always group sets of such variables into independent and identical distributed clusters of variables and, again, the result would be a Gaussian distribution. One exception is out from these Gaussian distributed situations (Voit, 2003): one where the size of these clusters is of the order of the total size of the system, i.e. when the second moment diverges, $E(X^2) \rightarrow \infty$, violating Lindberg condition and, consequently, all the stronger ones. For such kind of dependent processes instead of a Gaussian distribution, a α-stable Lévy distribution with $\alpha < 2$ and the typical heavy tails and power-laws is observed.

On a more ontological approach, when modeling financial and economical networks, random variables are translated into agents. Agent-based models for describing and addressing the evolution of markets has become an issue of increasing interest (Farmer and Foley, 2009) and appeals for further developments (Haldane and May, 2011; Johnson and Lux, 2011; Samanidou et al., 2007). They enable one to access three important questions (Bouchaud and Potters, 2003). First, the system is able in this way to be decomposed into sellers and buyers, a common feature of all finance systems. Second, one does not need to assume the system to be in equilibrium, which indeed is what we observed in real stock markets. Third, by properly incorporating the ingredients of financial agents and the trades among them one can directly investigate the impact of trades in the price, according to some prescribe scheme.

Here, we aim to choose a good model for the individual behavior of single financial agents, at a microscopic scale, in a way that the collective behavior generates an output in accordance with the observed curves of macroscopic variables, namely the financial indices.

Several of such bottom-up approaches were thoroughly investigated. The Solomon-Levy model (Levy et al., 1994) defines each agent as a wealth function $\omega_i(t)$ that cannot go bellow a floor level, given by $\omega_i(t) \geq \omega_0\bar{\omega}(t)$ where $\bar{\omega(t)}$ is the agent average ω at instant t and ω_0 is a proper constant. The imposition of the floor based on the mean field $\bar{\omega(t)}$ means that on average $\langle|w_i(t) - \bar{\omega}(t)|\rangle \sim N$ and, by basic statistics, $var(\omega(t)) \sim N^2$. Consequently, the result of the Solomon-Levy model, despite the interesting idea of the introduction of a floor similar to what was done by Merton (Merton, 1973) in the agent dynamics, will surely be a α-stable distribution with a power law heavy-tail,i.e., $\alpha < 2$. *A fortiori*, percolation based models like Cont-Bouchaud (Cont and Bouchaud, 2000) or Solomon-Weisbuch (Solomon and Weisbuch, 1999), by the nature of the phenomena, also brings up variations of system size order of magnitude and, obviously, will lead also to Lévy-type distributions. If a multi-agent model does not give additional information and only provides the distribution a system size second moment, there is no particular surplus in the application of such a model compared with a direct fitting of an α-stable Lévy distribution. Moreover, all complexity used to build in the individual behavior of the agents (Lux and Marchesi, 2000) will not contribute to the actual solution of the problem.

Following the above considerations, we can eliminate from our reasoning every microscopic scenario that result on either weak or strong forms of CLT that will result on a Gaussian distribution. What remains? Every microscopic scenario that generates a system size order variance, with a $\alpha < 2$ Lévy stable distribution having the observed heavy tails. For everything else we can choose arbitrarily our model composition, which opens a rather broad panoply of possibilities. This mathematical freedom to choose the model of the underlying mechanisms is only constraint by the requirement of bridging the biological foundations of an economic system and the behavior of a market curve. With such bridging we are able to anchor information from the market curve to established theoretical principles of economy without additional assumptions like in (da Cruz and Lind, 2011).

The question we are interested in is what is the minimum model for an economic system? In other words, what are the fundamental assumptions common to all economic systems? Do they suffice for the emergence of statistical features of macroscopic variables such as heavy-tails? Next we argue that there are three fundamental assumptions for an economic system of agents.

First, agents promote trading. Human beings are more efficient doing specialized labor than being self-sufficient and for that they need to exchange labor. The more labor exchanges they make the more specialized they can be. The usage of the expression 'labor' can be regarded as excessive by economists, but readers can look at it as the fundamental quantity that is common to labor, money, wage, etc. that justifies the exchange. Something must be common to all these quantities; if not, we wouldn't exchange them. The physicists can regard such fundamental quantity as an 'economic energy'.

Second, we only consume and produce a finite amount of the overall product. Thus, if an agent transposes that finite amount it loses his (consumption) trade connectivity in the economic environment in order to return to an admissible state that guarantee the finitude of the overall product within the system.

Third, human agents are different and attract differently other agents to trade. As we see bellow, this difference should reflect some imitation, where agents tend to prefer to consume (resp. produce) from (resp. for) the agents with the largest number of consumers (resp. producers). The number of producer and consumer neighbors reflects supply and demand of its labor, respectively, and combining both kind of neighbors should suffice to quantify the price of the labor exchanged.

In this paper we show that heavy-tailed return distributions are due to the economic organization emerging in a complex economic network of trades among agents governed under the above three assumptions. Further, we show that the power-law tails are characterized by an exponent that can be measured and is constrained by upper and lower bounds, which can be analytically deduced. The knowledge of such boundaries are of great importance for risk estimates: by deriving upper and lower bounds, one avoids underestimates which enable the occurrence of crisis unexpectedly and avoids overestimates which prevents profit maximization of the trading agents.

We start in Section 2 by discussing how the biological foundations of the existence of an economy are materialized into an economic organization topology. In section 3 we will show that an economic system behaves critically, transiting intermittently between two phases. Critical system combined with the underlying topology enable us to bound the behavior of the system, under topological constraints. Such boundary behavior leads naturally to a maximum and minimum value on risk evaluation, improving the knowledge about the uncertainty of the market future evolution. Finally, we will show how empirical data and computational results are in accordance with the analytical conclusions.

2 System Topology in Attractive Fields

If we look to corporate advertising or brand publicity actions one of the main characteristics is the usage of the volume of sales or the number of costumers as a motivating factor, though a large number of customers represent a higher demand and, consequently, a higher price, according to the Law of Demand and Supply. We feel encourage to buy something if we know beforehand that many other bought it already. The relative attractiveness of the demand is stronger than the repulsive effect it has on the price. Some authors in Economics call this phenomenon imitation (Bouchaud and Potters, 2003), while physicists call it *preferential attachment* and it was introduced by Simon (Simon, 1955) and developed by Barabási (Barabási and Albert, 1999).

In this Section we argue that imitation or preferential attachment is an universal principle in a multipoint attractive field environment, where each person, company or economic agent imposes an attractive field in the economical environment and it can be expressed by a well known probabilistic law.

For a better understanding, we take the human system as a general system of many bodies interacting through an attractive field. One starts by defining the potential function, based on a two body problem to get an Hamiltonian, the function that describes the dynamics of the system (Greiner, 2003). With such function and based on the existing interactions and their dynamic parameters – e.g. distance – the definition of the dynamics of the system is closed by means of principles like energy conservation and minimal action. In classical mechanics, what describes how planets orbit around stars or other planets? There is a well in the potential function that makes that one particular planet to be bonded to a particular start or bigger planet. But then two questions raise.

First, why is a particular planet trapped in a particular potential well since in a many bodies problem there are many potential wells where the planet can be in? Second, what forms the potential well in a problem where everybody in the system attracts everybody else?

If it is assumed that, besides the potential, no other kind of interaction or constraint exits, then the potential wells are formed exclusively by the same kind of interaction. Once the body is in a particular well, all related dynamics is well known since it is reduced to a specific two body problem.

Suppose now that the two body problem is not known or it is not possible to formulate a general solution for a two body problem, like in the case of economic interactions. Additionally, suppose there exists a generic system of $N \to \infty$ bodies, not necessary in equilibrium, such that each body i exerts an attraction force G_i over the other ones, depending only on an intrinsic quantity M_i of itself and seen by the others. Thus, $G_i \equiv G(M_i)$. At each point A, the total set of bodies will produce a field which sums up the contributions from all agents:

$$G(A) = \sum_{i=1}^{N} G(M_i). \tag{1}$$

When it is not possible to say more about G one expects that a body at A may orbit body i with a probability p_i given by

$$p_i = \frac{G(M_i)}{G(A)}. \tag{2}$$

Expression (2) lays in the heart of our approach, since it reduces the many-body problem to a probabilistic expression, mainly because the solution for the two body problem is not known besides the assumption that there exists an attraction force between them. A first order approximation, $G(M_i) \sim M_i$, leads to

$$p_i \approx \frac{M_i}{G(A)} \approx \frac{M_i}{\sum_{j=1}^{N} M_j}. \tag{3}$$

Equation (3) incorporates some of the physics behind the two-body problem. Since p_i is dimensionless, the property M_i behind the local strength of the field is arbitrary.

Even not knowing which property M_i is, it is possible to measure the probability p_i from Eq. (3). If M_i of a generic body i is relatively large when compared with the M's of the other bodies, then the number of bodies attracted by i will be large as well when compared with the other bodies. Assuming that the approximation in equation (3) is valid, then the relative number of bodies attracted by the body i represents the relative magnitude of M_i. As the number of bodies goes to infinity, the relative number of bodies effectively attracted by i converges to the probability for body i to attract other bodies.

According to the Law of Large Numbers, this number of neighbors divided by the total amount of agents will converge to a theoretical probability that, in our particular case, is given by (3). Therefore with no reason for believing otherwise, the number of neighbors is taken as a relative measure of the field strength, $M_i \sim k_i$, reducing Eq. (3) to

$$P_i = \frac{k_i}{\sum_{j=1}^{N} k_j}. \tag{4}$$

The expression (4) has been used as assumption on several previous works with the name of “preferential attachment” (Barabási and Albert, 1999; Dorogovtsev et al., 2000; González et al., 2006) or “imitation” (Bouchaud and Potters, 2003) for the representation of the natural tendency that humans have to connect to the ones that already have more connections. Here we argued that it is a general rule for attractive interactions, at least on a first order approximation.

There is an important consequence of this conclusion in terms of the topology of systems, namely it is possible to state (Barabási et al., 1999) that, if only this attractiveness is considered in the network, the probability of randomly finding a body with k_i connections is

$$P(k_i) \propto k_i^{-\gamma} \tag{5}$$

where γ is one exponent, characterizing of the system. We will show this result latter, as in (Barabási et al., 1999), since we will need it for the understanding of the criticality of the economic system.

A power-law as the one in Eq. (5) is a rather general law for the topology (structure) of a system with different bodies out of equilibrium, and it can be observed in many economic like systems as airports (Li and Cai, 2004) or the World Wide Web (Broder et al., 2000).

Thus, the important conclusion from these section is that, using the assumption that there is a biological surplus in exchanging labor (Lipsey and Chrystal, 2007) - or representative forms like money - that generates the natural propensity of economic agents (people) to interact and that this agents are different from each other, the consequence is that the bodies will organize themselves in a topology given by Eq. (5).

3 Non-Linearity and Critical Behavior

It has been observed by some authors (Sornette, 2003; Lux and Marchesi, 2000) the existence of critical behavior in stock market return distributions. Using a non-linear threshold of leverage similar to Merton's approach for the valuation of corporate debt (Merton, 1973) and the assumption that agents promote the exchange labor, here we show that the critical behavior exists in fact and it explains the heavy-tailed distributions of the stock market index curves.

We define an economic connection as an exchange of labor between two agents, say i and j, which dissipates an amount of energy U_i. Agent i delivers an amount of labor W_{ij} to agent j and gets a proportional amount of labor $E_{ij} = \alpha_{ij} W_{ij}$ where α_{ij} is the 'exchange rate' of labor. Figure 1 illustrates the economic connection between two agents.

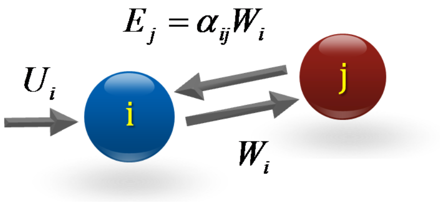

Fig. 1 Illustration of economic connections. Details in text.

Being directed from i to j, agent i takes the connection as a production or outgoing connection and agent j as a consumption or incoming connection. Assuming that each agent can connect to several other, since every agent will have the propensity to establish new economic links to get specialized labor from other agents, the "economic energy" balance equation on each agent i will be

$$U_i = \sum_{j \in L_{out}}^{k_{i_{out}}} W_{ij}(1 - \alpha_{ij}) + \sum_{m \in L_{in}}^{k_{i_{in}}} W_{mi}(\alpha_{mi} - 1) \tag{6}$$

where L_{out} is the set of neighboring agents to which i delivers labor and L_{in} the set of neighbors from which i gets labor. The energy in Eq. (6) has a straightforward parallel to the physical energy dissipated by the agent. Since energy and labor in this context have arbitrary units we approximate $W_{ij} = \langle W \rangle_{t=0}$, representing U_i in units of $\langle W \rangle$ as

$$U_i = k_{i,out} - k_{i,in} + \sum_{m \in L_{in}}^{k_{i,in}} \alpha_{mi} - \sum_{j \in L_{out}}^{k_{i,out}} \alpha_{ij}. \tag{7}$$

Assuming that the difference between any individual exchange rate of labor and the system average $\alpha = \langle \alpha_{ij} \rangle_{tot}$ is relatively small, we can make a mean-field approximation as

$$U_i = \beta(k_{i,out} - k_{i,in}) \tag{8}$$

with $\beta = (1 - \alpha)$. We must emphasize that we did not assume any additional assumption besides the ones that we need to justify the existence of an economy, we incorporate the economic or labor value in an energy function, since agents are physical entities that need to consume energy to generate labor.

Since the energy consumption is necessary to establish economic connections, agents cannot leverage themselves to infinity, i.e. one agent cannot consume more then a certain amount of labor from other agents. Thus, we define a relative threshold of leverage $U_{th,i}$ of an economic agent above which the other agents break their economic connections. We can regard this non-linear threshold as a limit for default, as in credit risk modeling (Vasicek, 1987). Let us assume that this threshold is defined as a function of the total turnover defined as

$$T_i = k_{i,out} + k_{i,in}, \tag{9}$$

which measures the amount of trades, both consuming and producing, that in total an agent makes. The threshold must be defined relative to this economic importance in a similar way as the usage of financial ratios as a measure of probability of default (Thomas et al., 2002). Thus each agent has a "relative" energy d_i which must obey

$$d_i = \frac{U_i}{T_i} \geq d_{th,i} \equiv \frac{u_{th}}{T_i}. \tag{10}$$

The exchange rate of labor α_{ij} can be taken as a dimensionless price. Since from Eq. (8) one can look at k_{in} and k_{out} as measures of supply and demand respectively, α_{ij} must grow monotonically with k_{out} and drop monotonically with k_{in}. Additionally, $\alpha_{ij} \geq 0$ and the first derivatives must decrease when $|k_{out} - k_{in}| \to \infty$. In other words, α_{ij} is a step function of $(k_{i,out} - k_{i,in})$ with α_{ij} to its maximal (resp. minimal) value for $k_{out} \gg k_{in}$ (resp. $k_{out} \ll k_{in}$).

So, our Ansatz for numeric simulation purposes is

$$\alpha_{ij} = \frac{\alpha_{max}}{1 + e^{-(k_{out,i} - k_{in,j})}} \tag{11}$$

which is basically a step function with average value at $\alpha_{max}/2$, similar to the one proposed by Cont-Bouchaud (Cont and Bouchaud, 2000). Henceforth we consider $\alpha_{max} = 2$ without loss of generality.

When Eq. (10) is not fulfilled, the agent loses its incoming connections and will not be able to pay to its neighbors that will stop "working" for him. When this occurs the following is imposed to the collapsed agent i and its neighbors, indexed as j:

$$U_i \to U_i + \beta k_{i,in} \tag{12a}$$

$$T_i \to T_i - k_{i,in} \tag{12b}$$

$$U_j \to U_j - \beta \tag{12c}$$

$$T_j \to T_j - 1. \tag{12d}$$

This "multi-agent" model of the economy is such that agents are not independent from each other. Their inter-dependence is here put in an intuitive form, through Eqs. (12) and basic assumptions in Economy justify completely Eq. (10): (i) agents tend to deal with each other, (ii) it is not possible for the system to consume infinite energy and, for that reason, a limit leverage for each agent must exist and (iii) agents have an attractiveness forming an attractive field with a given topology, in which we focus next.

Following the method by Barabási-Albert-Jeong (Barabási et al., 1999), at each time one new node enters the system and new connections are formed by the imitation attachment mechanism (Borland et al., 2005) defined in Eq. (4). The growing rate of connections to each agent is given by

$$\frac{\partial k_i}{\partial t} = m\Pi(k_i) = m\frac{k_i}{\sum_{j=1}^{N} k_j} \tag{13}$$

with N the total number of agents in the system. Since each connection affects two agents, the denominator in Eq. (13) obeys $\sum_{j=1}^{N} k_j = 2mt$ where t is the total system age. Then $\frac{\partial k_i}{\partial t} = \frac{k_i}{2t}$ with the solution

$$k_i(t) = m \left(\frac{t}{t_i}\right)^{\frac{1}{2}} \tag{14}$$

where t_i is the first instant when the agent i got into the economic network. Using the approach from (Barabási et al., 1999), the probability for an agent to have k neighbors is

$$P(k) = \frac{\partial}{\partial k} P(k_i < k) = \frac{\partial}{\partial k} P(t_i > \frac{m^2 t}{k^2}) = \frac{\partial}{\partial k}\left(1 - \frac{m^2 t}{k^2(t+m_0)}\right) = \frac{2m^2 t}{m_0 + t} k^{-3} \tag{15}$$

The exponent value three has an important meaning that we will address in Sec. 5. For now, we assume that the probability in (15) has a general exponent γ, yielding $P(k) \sim k^{-\gamma}$. According to Eq. (10) an agent will collapse, i.e. will lose their connections, if the following conditions are fulfilled:

$$k_{i,out} - k_{i,in} > u_{th}(k_{i,out} + k_{i,in}) \tag{16}$$

$$k_{i,out} - 1 - k_{i,in} \leq u_{th}(k_{i,out} - 1 + k_{i,in}) \tag{17}$$

or more simply

$$\omega k_{i,in} < k_{i,out} \leq \omega k_{i,in} + 1 \tag{18}$$

with $\omega = \frac{1+u_{th}}{1-u_{th}}$. Meaning that the probability for node i to collapse is

$$P_{br} = P(\omega k_{i,in} < k_{i,out} \leq \omega k_{i,in} + 1). \tag{19}$$

Since $k_{i,in}$ and $k_{i,out}$ are integers there is only one integer value for $k_{i,out}$ in the interval $k_{i,in} < k_{i,out} \leq \omega k_{i,in} + 1$, given approximately by $k_{i,out} \sim \omega k_{i,in} + \frac{1}{2}$ and leading to

$$P_{br} \approx m(\omega k_{i,in}))^{-\gamma}, \tag{20}$$

since $\omega k_{i,in} \gg 1$.

Having a node that collapses, if its number of neighboring agents expected to collapse is bigger than one, the system would be in permanent destruction. On the other hand, if that expected number is lower than one, the system would grow indefinitely, since simultaneously agents tend to create more connections. In the first case one is lead to a scenario where agents are self-sufficient and in the second case one leaded to a non-realistic situation of infinite energy consumption. The only possible state of economy is the one where the expected value of neighbor agents to collapse is precisely one, which corresponds to a critical state. Obviously, this is a theoretical state. In practice, the economic system will travel from one phase to the other, growing and dropping as economists always said and as everybody always experiences for good or worse.

Since the expected value must be equal to one then

$$\sum_{k_{i_{in}}=1}^{\infty} k_{i_{in}} P(k_{i_{in}}) P_{br} = 1 \tag{21}$$

and from Eq. (15)

$$\omega^{\gamma} = m^{\gamma} \sum_{k_{i_{in}}=1}^{\infty} (k_{i_{in}}))^{-2\gamma+1} m^{\gamma} \zeta(2\gamma - 1) \tag{22}$$

where ζ is Riemann Zeta function.

A similar derivation can be done for positive variations, instead of drops: instead of limiting the leverage to collapse, one limits the savings for a consumption chain of events that can lead to a heavy-tailed distribution with different exponents on the positive and negative side since the mechanisms are not dependent.

With expression (22) we show that, only by imposing first principles in Economy, $P1$, $P2$ and $P3$ above, the economic system is trapped in a critical state defined through the relation between economic growth m, leverage level ω and the economic organization characterized by γ. Furthermore, the critical behavior leads to aggregate measures based on the exchange of labor, like returns, which have an α-stable Lévy distribution. Differently from previous studies, here we focus on universal features of trading networks, without the need for more assumptions on agents like imposing them to be rational or irrational among other features. Nevertheless, we need to show that empirical distributions are in accordance with our conclusions. And, as we will describe next, they are in fact (da Cruz and Lind, 2010).

4 Exponent Amplification

Since we know that the economical network is in a critical state, transiting between two phases we can look how the microscopic mechanisms that make neighbor agents to collapse generates the heavy-tails. Such mechanisms should be the same for the emergence of bubbles, but here we focus only in the negative part of the fluctuations distribution.

The collapse of a node leads to the breaking of its consumption links or, equivalently, its neighbors' production links. Meaning that each collapse will provoke a chain reaction of size r, i.e., it originates a branching process as illustrated in Fig. 2 with a probability according to Otter's theorem (Otter, 1949), given by (Otter, 1949; Harris, 1963; Athreya and Ney, 2004; Lauritsen et al., 1996)

$$P(Z = r) \propto r^{-\frac{3}{2}} \tag{23}$$

where Z is the total number of nodes involved in a single branching process. Equation (23) holds independently of the topology as long as the branching process is critical, but the number of collapsed agents in a real economic network is difficult to recount for. In the economical

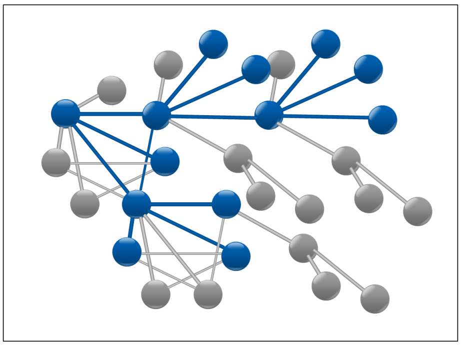

Fig. 2 Illustration of a collapse chain reaction.

context, one chain reaction is called a "crisis" and "avalanche" in the physical context. Henceforth, we address to them as crisis or avalanches indistinctly.

What is measured when an avalanche occurs in such a real network is the number of links destroyed during the avalanche. This number of links accounts for a macroscopic property of the system, namely the overall product U_T which sums up all outgoing product of all agents. Therefore, we want to express $P(Z)$ in terms of the total number of destroyed links.

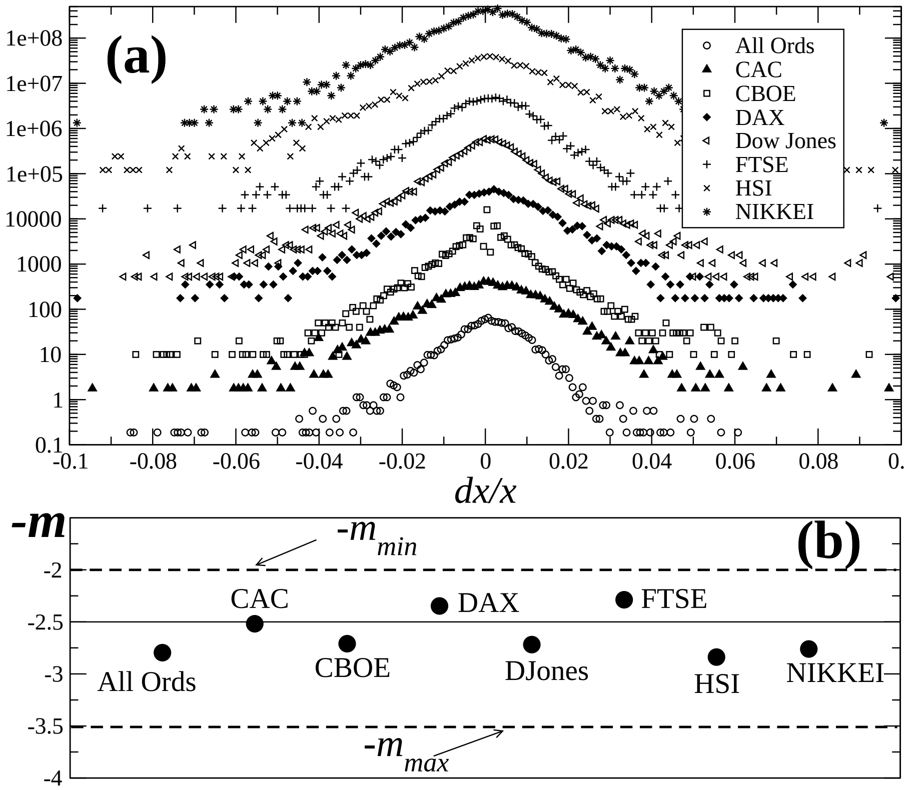

Fig. 3 **(a)** Heavy-tails of stock indexes cumulative distributions and **(b)** the corresponding exponents. Distributions in (a) are shifted in the vertical axis for easy comparison. Solid line in (b) indicates the theoretical value obtained for $\gamma = 3$ (see Eq. (25)), while dashed lines indicate the bounding values of m for $2 < \gamma < 3$.

From the total number r of nodes included in one avalanche, since $P(k) \sim k^{-\gamma}$, the number of nodes with k_j connections involved in the avalanche is $n_j = r k_j^{-\gamma}$ which corresponds to $k_j n_j = r k_j^{-\gamma+1}$ destroyed links in nodes with k_j links. Thus, the total number of links destroyed is given by

$$K_T = r \sum_{j=k_{min}}^{k_{max}} k_j^{-\gamma+1} \tag{24}$$

where k_{min} and k_{max} are the lowest and highest degree involved. Since the sum on the right side of (24) are the degrees, not the links, we can substitute each k_j by $\alpha_j K_T$, where α_j are leverage dependent coefficient, which leads to $r \propto K_T^{\gamma}$, i.e. $P(K_T) \propto K_T^{-\frac{3}{2}\gamma}$.

So, the fraction of avalanches of size – number of lost links – larger than size s is given by

$$P(K_T \geq s) \propto \int_s^{+\infty} x^{-\frac{3}{2}\gamma} dx \propto s^{-\frac{3}{2}\gamma+1} \equiv s^{-m} \tag{25}$$

Equation (25) should hold for all types of trades and macroscopic observables of the economical product in one economic network. Figure 3 presents data from several stock market indexes. Figure 3a shows the probability density functions (PDFs) of the logarithmic returns of each index, symbolized as x, where one can observe the heavy-tails. While the heavy-tailed shape of the return distributions was already known (Mandelbrot, 1997), at least within a good approximation, the explanation for their emergence was up to our knowledge not addressed till now.

The result in Eq. (25) relates the microscopic economic relations – trades among agents – with the form of the heavy-tailed return distributions. This relation emerges from the interplay between the distribution of the returns, one macroscopic quantity chosen as the overall product U_T, and the topology of the social network. The economic connection was defined as one exchange of labor, in one of its forms. No additional assumptions were taken. Since we never made any conjectures regarding the specific type of economic interaction.

Figure 3b shows the exponent $m = \frac{3}{2}\gamma - 1$ in Eq.(25) for each one of the stock market indexes. All of them take values around the theoretical prediction $m = 5/2$ for a topology with $\gamma = 3$. Further, all values lay between to bounds, $m_{min} \equiv 2 < m < \frac{7}{2} \equiv m_{max}$, as we explain in the next section.

5 Distribution Boundaries

In previous sections we saw how from first principles in Economy, namely that economic agents are impelled to exchange economic value in the form of labor, wealth, or other (Lipsey and Chrystal, 2007) and that they do that according to a imitation procedure, which we translated as a preferential attachment among agents, which yields the probabilistic law in Eq. (4). This was possible because it is not possible to know the nature of the labor W_i, and therefore Eq. (4) contains all information about the labor of each agent necessary to establish the organization of the bodies in a general economic problem, where a financial problem is just a particular case.

The form of the agent topology is defined through Eq. (5). But there is still an open issue: which values of γ are admissible in an evolving network of economic trades and collapses? Observed economic networks show that typically $2 < \gamma < 3$ (Albert and Barabási, 2002; Li and Cai, 2004) but that empirical evidence is not enough to estimate the risk associated the exponent of crisis sizes. In this section we show the topological causes that underlay the emergence of those bound values.

We know (Albert and Barabási, 2002; Dorogovtsev et al., 2000) that economic like complex networks exhibit a self-similar topology that can be translated into the probability power-law given in Eq. (5). Because of this self-similarity, the same network topology is observed independently of the scale. The study of self-similarity in complex networks is done by getting the law that keeps nodes, links and their relationship invariant in scale. See illustrations in Fig. 4. To this end, we separate the two cases of directed and undirected networks and use the renormalization method by Song, Havlin and Makse (Song et al., 2005).

In directed networks, for each node links are either outgoing or incoming, the probability of a node to have k outgoing links – or correspondingly k incoming links – depends also in the scale p one is considering the entire network. The plot a) in Fig. 4 illustrates how unitary sets of agents compose a self-similar network of directed edges.

Since in directed networks the number of probable states grows with the number of nodes (see Fig. 4) then we can derive the scale invariant law as

$$\frac{dNP_d(p,k)}{dp} = 0 \tag{26}$$

meaning that the the node density in k-space $NP_d(p,k)$ is a scale invariant measure, corroborating some previous results (Song et al., 2005; 2006).

Plot b) in Fig. 4 illustrates the same as plot a) but this time for undirected edges. For undirected networks, however, the degree law $P_b(p,k)$ is the probability for a node to have k start links *or* k end links indistinctly. Undirected networks can be regarded as compositions of two directed networks, each one with an equal directed degree law $P_d(p,k)$. When one link is add or removed, affecting a node with degree k in one of the directed networks, it changes also a node with degree k'.

As described in Fig. 4 we can see that the renormalization generates N^2 admissible states when going from one scale to the next, since now each node can

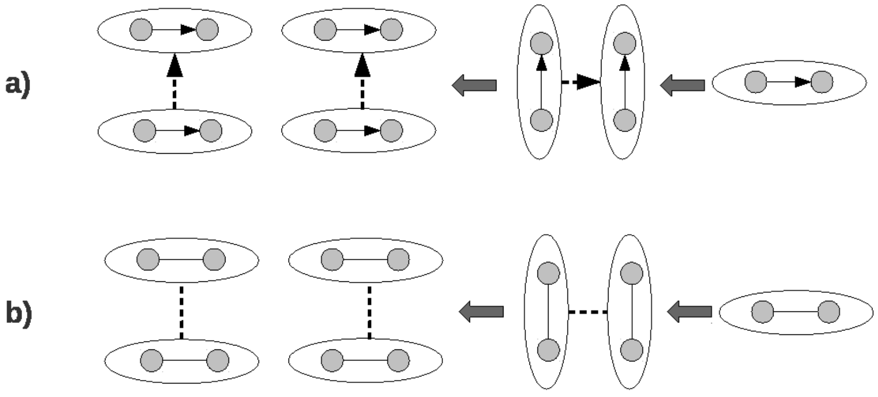

Fig. 4 Illustration of renormalization in complex networks. Dashed connections are the ones that disappear as one goes down in scale. **a)** For a directed network, the number of probable states grows with the number N of renormalized nodes, since only the left nodes on the first step and the lower node on the second step contribute to the number of probable states. **b)** For an undirected network, the number of probable states grows with the square of the number of renormalized nodes N^2, since all nodes in all steps contribute to the number of probable states.

connect to any other and simultaneously be connected from any other and the scale invariant law is

$$\frac{dN^2 P_b(r,k)}{dr} = 0. \tag{27}$$

In short, the self-similar transformation of the node degree, i.e. the number of links in a node will be ruled by

$$N^q P_d(k)dk = N_p^q P_d(k_p)dk_p \tag{28}$$

where k and k_p are, respectively, an original and renormalized quantity of links and N and N_p are the correspondent quantity of nodes. The exponent is $q = 1$ for directed networks and $q = 2$ for undirected networks.

Since the power-law in Eq. (5) is invariant under renormalization,

$$P(k) \to P(k_p) \propto k_p^{-\gamma} \tag{29}$$

and if the renormalization of the links are expressed as (Song et al., 2005) $k \to k_p = \alpha_p k$, renormalization will result in

$$N^q = N_p^q \alpha_p^{-\gamma+1}. \tag{30}$$

We now define l_B as a distance in the economic space between nodes, which equals the average number of links separating a randomly chosen pair of agents. The fractal dimension d_B of the network can then be calculated (Song et al., 2005) using a box-counting technique (Falconer, 1997) as

$$N_p = N l_B^{-d_B} \tag{31}$$

and the links will scale as

$$k_p = k l_B^{-d_k} \tag{32}$$

which yields $s_p = l_B^{-d_k}$. Thus, using Eqs. (5), (28), (31), and (32), the γ value can be obtained as a function of the fractal dimension of the system as

$$\gamma = 1 + q\frac{d_B}{d_k} \tag{33}$$

where $q = 1$ for directed networks and $q = 2$ for undirected networks (Song et al., 2005).

Next, we show that this result retrieves a topological constraint for the value of γ and, consequently, for the ‘weight’ of the heavy-tail in the crises size distributions given by Eq. (5).

Let us suppose (wrongly) that economic networks are unweighted, i.e. all links are equal. It can be proved (Albert and Barabási, 2002; Dorogovtsev et al., 2000; Barabási et al., 1999) that adding a node with a link to an existing node chosen through a preferential attachment probability (Barabási and Albert, 1999) will lead to a topology with degree distribution given by Eq. (5) with $\gamma = 3$. That is coherent with our result (33) since adding one link for each node will make links to scale like nodes, meaning that $d_B = d_k$ and $\gamma = 3$ because at the end of each link there is a node and for each node there is a link, except for very few seed nodes (Albert and Barabási, 2002).

If one assumes that connections between pair nodes do not depend on their connectivity or, equivalently, all nodes have the same connectivity then for a set of N nodes we find $N^2 - N$ links since all nodes connect between them. Thus, the links scale with $N^2 - N \sim N^2$ when $N \to \infty$, yielding $d_k = 2d_B$, i.e. $\gamma = 2$.

Since in an economic network links are not all equal, the considerations above imply that we should expect values of $\gamma < 3$ in real economies. Preferential attachment and maximum number of random links are the two extreme situations of a spectrum of possibilities corresponding to values of γ in the interval $2 < \gamma < 3$.

Additionally, if we assume that more than one type of connections can coexist, the final γ can assume a value under the limit 3, which supports studies on empirical economic indices (da Cruz and Lind, 2010).

This is an important result since, independently from the complexity associated with economic processes and with the network of economic relations, we can bound the return distribution and, thus, find a closed risk measure.

6 Conclusion

In this paper we establish the bridge between basic economic principles and the heavy-tails of the return distributions whose exponent values are bounded. The boundary values measure the model risk associated with any model.

We showed that using only the assumption that economic agents attract each other to exchange labor, which is the fundamental assumption for the existence of an economy (Lipsey and Chrystal, 2007), then economic links tend to be distributed according to a power-law.

We argued that return distributions with heavy-tails observed empirically, emerge from the aggregation of dependent random variables, which has variance diverging with the system size. Consequently, for preventing the system from diverging, there is a wealth threshold for each economic agent, exactly as predicted by Merton for corporate debt modeling (Merton, 1973).

Combining both findings - wealth threshold and power-law - we showed that the exponent is limited to $2 < \gamma < 3$. Since the exponent m of the heavy-tails for cumulative return distributions (sizes of crises) is given by $3\gamma/2-1$, we showed that $2 < m < 3.5$. Consequently, the heavy-tails observed in the return distributions assume values between 3 and 4.5.

These findings help to solve the controversy about Mandelbrodt hypothesis (Mandelbrot, 1997) that the distribution of financial returns are explained by Lévy distributions, and therefore would yield an exponent smaller than 3. Some arguments against Mandelbrot hypothesis were based (Borland et al., 2005) in empirical measures of the return distributions, yielding exponents larger than 3. As summarized in the previous paragraph, our findings show the same range of exponent values. Still, we think that Mandelbrot was right. Though what we measure for the time series of returns are links between agents (corresponding to exponents larger than 3), the random variables behind Lévy distributions are the agents, which corresponding to the exponent γ (smaller than 3). This work bridges these two apparent contradictory positions.

Finally, since the exponent is bounded, the total risk associated with the process being observed is also bounded between a lower and one upper boundary values. This is perhaps the most interesting result from our work: Having boundaries for the heavy-tailed return distributions we can actually measure model risk, since the economic organization has topological limits.
